PAWS is a tool to analyse the behaviour of weighted automata and conditional transition systems. At its core PAWS is based on a generic implementation of algorithms for checking language equivalence in weighted automata and bisimulation in conditional transition systems. This architecture allows for the use of arbitrary user-defined semirings. New semirings can be generated during run-time and the user can rely on numerous automatisation techniques to create new semiring structures for PAWS' algorithms. Basic semirings such as distributive complete lattices and fields of fractions can be defined by specifying few parameters, more exotic semirings can be generated from other semirings or defined from scratch using a built-in semiring generator. In the most general case, users can define new semirings by programming (in C#) the base operations of the semiring and a procedure to solve linear equations and use their newly generated semiring in the analysis tools that PAWS offers.

1 Introduction

In recent times, modelling techniques have shifted from a purely acceptance-based reasoning to one that takes various notions of weight and quantities into consideration. The theory of weighted automata gives rise to a flexible framework, where acceptance behaviour can be quantified in numerous ways. Probabilities are commonly used to express the likelihood of making a given transition, whereas the tropical semiring is commonly used to denote the cost of making a transition. Due to the great variety of semirings the theory of weighted automata can be applied to a multitude of different fields of interest, such as natural language processing, biology or performance modelling (see e.g. [12]). Typical questions regarding weighted automata concern their language (or traces), for instance language equivalence. Due to the generality of the notion of weighted automata, they are a versatile means for modelling purposes, though decidability results are not as strong as for non-deterministic automata. In particular, it is well known, that language equivalence is an undecidable problem for weighted automata [16]. This, however, is not a damning result for language equivalence, since it is also well-known that language equivalence is decidable for many other semirings such as the two-valued boolean algebra (for which weighted automata are just nondeterministic finite automata) or fields (where decision procedures run in polynomial time [14, 7]). PAWS[1] is a tool that offers algorithms to decide language equivalence and the threshold or universality problem for weighted automata.

Based on our previous work in [15] and [5], the tool PAWS implements two different approaches to language equivalence checks for weighted automata. One approach employs a backwards search assuming at first that all states are language equivalent and exploring words from the end to the beginning to determine non-equivalent pairs of states, similar to partition refinement. Different from usual partition refinement algorithms, this algorithm does not necessarily terminate at the moment when the partitions cannot be further refined in one step, because refinements can happen at a later point of time. The termination condition has to be chosen differently here, and as expected, the algorithm does not necessarily

terminate for all semirings (see the undecidability result by Krob [16]). However, for many semirings it does and in either case it is always a suitable semi-decision procedure for the absence of language equivalence. This approach is closely related to the line of work started by Schützenberger, [18] and later generalised in [3], using the notion of conjugacy.

Additionally, PAWS offers a second approach to decide language equivalence [5]. This approach stands in the tradition of Bonchi's and Pous' seminal work on equivalence checks for NFAs using up-to techniques [6]. Here, a language equivalence relation on vectors is built, starting from the initial pair of vectors suspected to be language equivalent. As the algorithm progresses, it builds up a language equivalence relation similar to a bisimulation relation and stops at the moment when a suitable relation proving language equivalence is found, or a witness to the contrary is found. The algorithm works up-to congruence and therefore prunes the relation on-the-fly, dropping redundant vector pairs. The flexibility of this optimised variant of the algorithm is reduced when compared to the partition refinement algorithm, but it can still be used for a variety of user-generated semirings, such as rings and l-monoids, and can lead to an exponential speed up in some cases. Based on a similar approach, PAWS also offers a decision procedure for the universality problem for weighted automata over the tropical semiring of the natural numbers, which is potentially exponentially faster than a naive approach due to Kupferman et al. [2]. The universality problem checks whether from a given starting vector, all words have a weight smaller than or equal to a given threshold.

Finally, PAWS also considers conditional transition systems, which, rather than adding weights to transitions, extend traditional transition systems by means of conditions, or product versions to enable flexible modelling of software product lines, while taking possible upgrades between different products of a software product line into account [8]. For these kinds of systems, bisimulation rather than language equivalence is considered, because the user experience for different products is in the focus. The bisimulation check can be performed on any finite distributive lattice defined via its set of join irreducible elements. Alternatively, a BDD-based implementation of (certain) lattices is offered and allows for a significantly faster bisimulation check as presented in [4]. Again, the bisimulation check is parametrised over the lattice used and can accept any lattice, either defined directly via its irreducible elements, or using the BDD-based approach, as input.

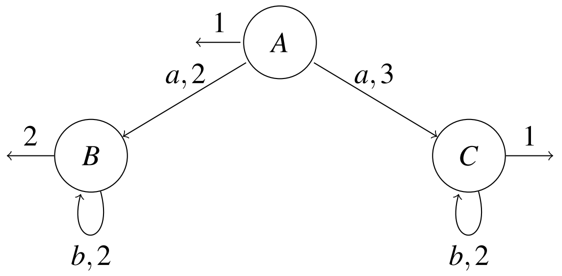
A key feature of PAWS is its extensibility. The algorithms are parametrised over the semiring and it is therefore possible to use the algorithms PAWS offers, not only for the semirings that come pre-implemented, but also for newly generated semirings. For that purpose, PAWS offers ways of adding new semirings and executing algorithms for these semirings. All algorithms are implemented generically and can be used for various semirings or l-monoids, provided all necessary operations such as addition, multiplication, and solving linear equations are specified. Therefore, PAWS is equipped with a semiring generator that allows to generate new semirings that are not pre-implemented and to define weighted automata or conditional transition systems over these. Specifically, we have built several layers of automatisation, so that whenever one, e.g., defines a complete distributive lattice, it suffices to give a partial order, from which the lattice of downward-closed sets is generated [11] and all operations are provided automatically. Building semirings from other semirings using crossproducts is almost completely automatised and modulo rings are automatised using Hensel liftings [10]. In addition, it is possible to add arbitrary semirings by providing code for the operations mentioned before.

2 Preliminaries: System Types and Decision Problems

Here we give a short overview over the systems that PAWS can analyse, i.e. weighted automata and conditional transition systems. For that purpose we require the notions of semirings and distributive lattices.

- A *semiring* is a tuple $\mathbb{S} = (S, +, \cdot, 0, 1)$ where $(S, +, 0)$ is a commutative monoid, $(S, \cdot, 1)$ is a monoid, 0 *annihilates* $\cdot$ (i.e., $0 \cdot s_1 = 0 = s_1 \cdot 0$) and $\cdot$ *distributes over* $+$ (i.e., $(s_1 + s_2) \cdot s_3 = s_1 \cdot s_3 + s_2 \cdot s_3$ and $s_3 \cdot (s_1 + s_2) = s_3 \cdot s_1 + s_3 \cdot s_2$, for all $s_1, s_2, s_3 \in S$).
- A *complete distributive lattice* is a partially ordered set $(L, \sqsubseteq)$ where for all subsets $L' \subseteq L$ of L the infimum $\bigsqcap L'$ and the supremum $\bigsqcup L'$ w.r.t. the order $\sqsubseteq$ exists and infimum distributes over finite suprema: $(\ell_1 \sqcup \ell_2) \sqcap \ell_3 = (\ell_1 \sqcap \ell_3) \sqcup (\ell_2 \sqcap \ell_3)$ for all $\ell_1, \ell_2, \ell_3 \in L$. Together with $\top = \bigsqcup L$ and $\bot = \bigsqcap L$, a complete distributive lattice forms a semiring $\mathbb{L} = (L, \sqcup, \sqcap, \bot, \top)$.
- An l-monoid is a lattice $(L, \sqcup, \sqcap, \bot, \top)$ together with a monoid $(L, \cdot, 1)$ such that $\cdot$ distributes over $\sqcup$. If $\bot$ annihilates $\cdot$, i.e. $\bot \cdot \ell = \bot$ for all $\ell \in L$, then the l-monoid can be regarded as a semiring $(L, \sqcup, \cdot, \bot, 1)$.

A weighted automaton (WA) can be understood as a non-deterministic automaton that additionally carries weights from a given semiring $\mathbb{S}$ on each transition, as well as a termination weight for each state. Rather than accepting or rejecting a word w, a state x in a weighted automaton associates it with a value from $\mathbb{S}$. This value can be obtained as follows: Take the sum of the weight of all w-labelled paths p starting in x. The weight of a path p is the product of all transition weights along p, including the termination weight. Consider for instance the following simple weighted automaton over the field $\mathbb{R}$:



The weight of the word ab in state A can be computed as follows: there exist two paths to consider, (A, a, B, b, B) and (A, a, C, b, C). The first path has the weight $2 \cdot 2 \cdot 2 = 8$ and the second path has the weight $3 \cdot 2 \cdot 1 = 6$, so overall, the weight of the word ab in A is $8 + 6 = 14$. For weighted automata, PAWS offers an algorithm to decide which pairs of states are language equivalent, i.e. assign the same weight to all words. In general, this problem is undecidable, but for many specific semirings (e.g. the reals) it is decidable.

PAWS offers two algorithms to decide language equivalence. The more generally applicable algorithm called *Language Equ.(Complete)* in the program, can be applied to any semiring and yields, if it terminates, a complete characterisation of language equivalence in the automaton.

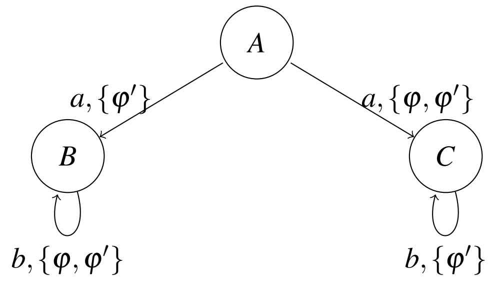
For complete and completely distributive lattices, and more generally, completely distributive l-monoids, an optimisation up to congruence is available (*Language Equ.(Up-To)*). This algorithm checks whether two initial vectors are language equivalent by building a language equivalence relation and pruning the relation by congruence closure, i.e. pairs of vectors that are already in the congruence closure of previously found pairs of vectors, are discarded.

One semiring, where language equivalence is undecidable is the tropical semiring over the natural numbers $(\mathbb{N}_0 \cup \{\infty\}, \mathsf{min}, +, \infty, 0)$, as shown by Krob [16]. However, the universality problem is decidable in this case. The universality problem asks, for any given number $n \in \mathbb{N}_0$, whether the weight of all words from a given starting vector is bounded by n.

All algorithms for these problems require a method for solving linear equations over the semiring.

PAWS also analyses a second type of systems: conditional transition systems (CTS) [4, 1]. CTS are defined over a finite partial order of conditions. Each transition is assigned a downwards closed set of conditions under which the transition may be taken. Before execution, one condition is fixed and all transitions that carry the respective condition remain active and all other transitions remain inactive. Afterwards, the CTS evolves just like a traditional labelled transition system. At any point though, a change of conditions can occur by going down in the order. If the condition is changed, so do the active transitions and additional transitions may become available. Note that due to the requirement that all transitions carry a downwards closed set of conditions, only additional transitions can appear, no transition can be deactivated by performing a change in conditions. Therefore this change of conditions can be considered as an upgrade of the system. Also note the strong relation to complete distributive lattices: Every finite partial order gives rise to a lattice by considering all downwards closed sets of elements ordered by inclusion. And vice versa, every finite distributive lattice can be represented in this way [11].

Now consider the following CTS defined over the set of conditions $\{\varphi, \varphi'\}$, where $\varphi' \leq \varphi$.



Furthermore assume we are starting in state A and under the initial condition φ. Then only the transitions from B to B and from A to C are available. If we choose to make a step from A to C via the a-labelled edge, we cannot do any further steps, unless we first perform an upgrade to φ', which allows us to use the b-loop in state C.

For CTS we are interested in conditional bisimulation. Two states are conditionally bisimilar, if there exists a conditional bisimulation relating the states. A conditional bisimulation is family of traditional bisimulations R_φ, one for each condition φ, on the respective underlying transition systems. For two conditions $\varphi' \leq \varphi$ it must hold that $R_{\varphi'} \supseteq R_\varphi$, which intuitively means that if two states are bisimilar under φ, they must also be bisimilar under every smaller condition φ'. Furthermore, the standard transfer property for bisimulations must be satisfied.

In [4] we have shown how to model a small adaptive routing protocol as CTS.

Summarizing, the problems PAWS solves and the corresponding algorithms and semirings are displayed in the following table:

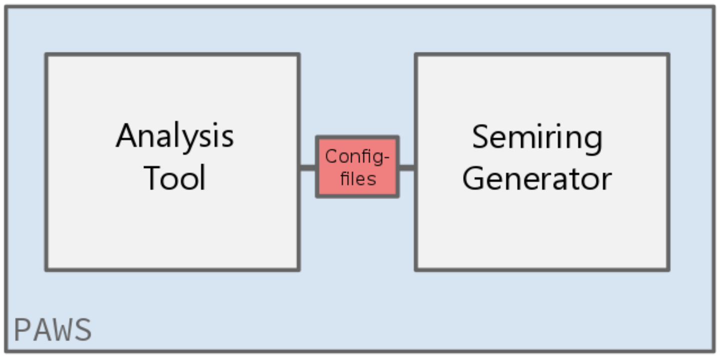
Problem	Algorithm	Semiring	Model
Language equivalence (all pairs)	*Language Equ.(Complete)*	any semiring	WA
Language equivalence (initial vectors)	*Language Equ.(Up-To)*	l-monoids, lattices	WA
Universality Problem	*Universality*	Tropical Semiring	WA
Conditional bisimilarity	*CTS Bisimilarity*	finite lattice	CTS

3 Design and Usage

In this section, we give an overview of some design decisions and the usage of the tool. First, we mention the basic structure of the tool and then discuss some of the problems and math-related features of the tool. Furthermore we explain how to work with PAWS.

3.1 Design

PAWS is a Windows tool offering a complete graphical interface, developed in Microsoft's Visual Studio using C#. The program is divided into two autonomous components:



Both components are designed according to the MVC pattern. In the sequel, we will discern these two program parts, as their interaction is rather limited, allowing them to be considered as separate concerns.

3.1.1 The Semiring Generator

The development of the semiring generator started in a master's thesis [17]. It supports five different generation processes, which, for clarity, are equipped with five separate input forms. The semiring generator supports three fully automated cases:

- Direct products
- Fields of fractions
- Field extensions for $\mathbb{Q}$

Furthermore, there are two options to generate code based on user implementations:

- l-monoids
- Arbitrary semirings

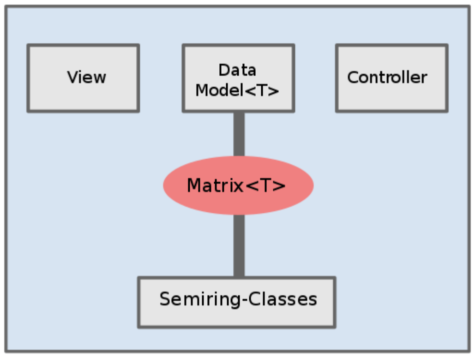
For the generation of source code we use *CodeDOM* of the *.NET* Framework, which enables code generation based on object graphs. The five processes are implemented via one superclass and three derived classes. The superclass contains all methods for creating if-statements, for-loops or useful combinations of these, based on predefined patterns. Except for the direct product generator, every class uses the constructor generating methods of the superclass. Most of the differences between the classes are reflected in the methods for generating the binary operators. Concerning methods for solving linear equations we are offering two templates: a naive implementation of the Gaussian algorithm and one method for l-monoids, based on the residuum operator [9].

With code generation, one always has to face the question of how to give the remaining program, i.e., the analysis component of PAWS, access to the newly generated classes. We decided to use the *Microsoft.Build.Execution* namespace for updating the analysis tool. This decision avoids creating multiple DLL files, which would be the case with a pure reflection-based solution to the problem. However, reflection is used to solve another difficulty. Due to the combination of different semirings or data types as elements of a new semiring, a dynamic approach is required to enable the automated generation of constructors with a string parameter, specifying the semiring value.

PAWS also manages the names of the semiring classes in individual text files. First, this prevents a user from overwriting an already fixed class name. Another advantage is that by using *System.Activator*, an instance can be created dynamically during runtime without knowing the class name at the level of program design. Hence, both parts use consistent config files, which is ensured by updating the corresponding config file if one of the program parts creates or deletes a semiring. But when deleting a semiring that has already been used to create and store an automaton or transition system, conflicts may occur with the serialised objects and thus with the user's storage files. Therefore, deletion of semirings must be dealt with separately. A semiring can only be deleted or modified if it has not been used in the previous session within an automaton.

3.1.2 The Analysis Tool

As already mentioned, for both program parts MVC is used to implement the user interface. The main focus of PAWS is to give the user the tools to define an automaton in order to be able to subsequently analyse it with the supported algorithms. In order to implement this as dynamically as possible, we have opted for a generic implementation. Therefore, the class $Matrix\langle T\rangle$ (where T is the generic type of the semiring), which implements automata in a matrix representation, is the core of the tool's architecture.



The main argument for the generic approach is that the algorithms for analysis of an automaton are based on the basic operators of a semiring. A further method is needed to solve systems of linear equations, which is also defined for each semiring within PAWS. It is therefore recommended to use a generic class that includes all the methods of analysis, which in turn dynamically call the corresponding operators or methods of the currently used semiring. This dynamic approach is thus combined with reflection.

Therefore, the management of automata created by the user requires a generic implementation as well. The *Model* for the matrices is therefore also generic and thus it makes sense to manage several semiring models by the controller.

Because of the generic approach, automatically checking the correctness of the user input proves to be problematic when the user has generated his or her own semiring and has implemented a string constructor to read semiring elements from input strings without input verification. In this case PAWS can not check whether the input is well-formed, this has to be taken care of in the user-implemented method. Such semirings can not be further used to generate other semirings.

A further design decision is that one can create finite semirings directly within the analysis component of PAWS. The reason why we chose to not move this option to the generator is that for finite lattices and modulo semirings over the integers no new classes have to be generated nor is there any need for new source code at all. In this case, it is sufficient to configure template classes for the corresponding semirings via static variables that contain the required information about the semiring. The operators are designed to behave according to the configuration of the class. In such cases, the analysis program must also access the configuration files in order to make the extensions known to the semiring generator.

As an additional feature, we have also integrated GraphViz[2] into the tool, as it allows visualization of weighted automata, if desired by the user.

3.2 Usage

We will discuss the usage of the tool separately for the two individual components of PAWS, hence this section contains subsections giving details about the following two components.

- The *semiring generator* to build and provide the required semirings over which automata can be defined. This generator is used to generate semirings that cannot be obtained in a fully automated way and supports some automatic generations.
- The *analysis tool* that allows the user to choose a previously generated semiring, one of the semirings that come built-in with the PAWS or to build a lattice and then to define automata in a matrix representation over those lattices. Matrices are then interpreted as weighted automata or conditional transition systems (CTS) and can be used to compute language equivalence for weighted automata with two different approaches, decide the threshold problem for weighted automata over the tropical semiring of natural numbers or to compute the greatest bisimilarity of a CTS.

3.2.1 The Semiring Generator

The semiring generator is used to generate the semirings under consideration. In order for a semiring to be usable within the context of PAWS, the structure needs to define the following components:

- A universe which contains all elements of the semiring. All predefined datatypes from C#, as well as combinations of them can serve as universes.
- An addition operator $+$ of the semiring.
- A multiplication operator $*$ of the semiring.
- One() and Zero() methods, which return the units of addition and multiplication.
- A method for solving linear equations over the semiring.

While the first four components are necessary to define a semiring in a mathematical context either way, the procedure to solve linear equations is an additional requirement – one that PAWS aims at reducing as much as possible – but in order to provide the greatest amount of flexibility possible, the tool offers the option to define a procedure to solve linear equations from scratch.

Attribute [✓]

Arbitrary Semiring [✓]

3.2.2 The Analysis Tool

The analysis component is designed to offer generic algorithms applicable to numerous predefined or user-defined semirings. Some of the algorithms can however only be used with specific (types) of semirings. The most general algorithm is the language equivalence check, for which all semirings are eligible. Conditional Transition Systems are only defined over lattices, therefore, the bisimulation check is limited to lattice structures. However, the user still has the choice between two different ways of dealing with lattices: representing elements of the lattice as downwards closed sets of irreducibles via the Birkhoff duality [11], applicable to all finite distributive lattices, or represented using binary decision diagrams (BDDs). The BDD variant is more restrictive and only designed for the application to CTS. Here, the irreducibles are required to be full conjunctions of features from a base set of features, ordered by the presence of distinct upgrade features. Lastly, the threshold check can only be performed over a single semiring, the tropical semiring over natural numbers.

The general workflow of the analysis tool is as follows:

- ▷ Choose a semiring
- ▷ Generate a matrix over this semiring, representing a weighted automaton or a conditional transition system

  Alternatively: Choose the matrix from a list of matrices that have been generated previously
- ▷ Start the algorithm and provide – if necessary – additional input

Additional input comes in two forms: starting vectors and the threshold to be checked against in case of the threshold algorithm. Depending on the semiring of choice, questions regarding language equivalence might not be decidable, leading to non-termination of the corresponding procedure in PAWS. In order to deal with this problem and to allow abortion of an overlong computation, the actual computation is delegated to a separate thread that can at any time be aborted by clicking a red button labelled “Abort”. In that case all intermediate results are discarded.

Matrix1	LatticeZ

Note that only the two language equivalence-based algorithms can run into non-termination issues. For the CTS bisimulation check, as well as the threshold problem on the tropical semiring of natural numbers, termination is always guaranteed. However, the runtime of CTS bisimulation check can be doubly exponential in the number of features under consideration – because the lattice is the set of all possible configurations, which in turn are all possible conjunctions over the features. Using the BDD-based implementation of lattices – which is particularly suited to the needs of CTS modelling – this explosion is mitigated in many cases, but it can not be ruled out completely. On the other hand, the BDD-based modelling only allows for special lattices to be modelled, i.e. those that arise as the lattices built from a set of features and upgrade features, whereas the variant called *FiniteLattice* allows for arbitrary (finite, distributive) lattices to be represented. In this case, lattices are represented via the partial order of irreducible elements, using Birkhoff's representation theorem [11].

Here we do not give any runtime results, but refer the reader to [4, 5] where we describe several case studies and list runtime results.

4 GUI Overview of PAWS

In this section, we demonstrate the handling of the various features and options that PAWS offers. First, we will present the semiring generator. In this case, we briefly explain a fully automated generation and the even more complex case, in which, apart from the constructor, the user has to specify the implementations on his or her own. We then illustrate the various possibilities to use the analysis component of PAWS in a short overview.

4.1 The Semiring Generator

First, we consider a fully automated generation demonstrated by the direct product input-mask (Figure 1 and 2). Then, in Figure 3 the console informs the user that the generated source code is compilable. In case the user specifies some code on his or her own, the console will display suitable compile error messages. Figures 4 and 5 depict the use of the input mask for user-dependent implementations.

4.2 The Analysis Tool

In this section the use of the PAWS analysis component is presented in a brief overview. The illustrations serve to explain our intuition behind the design and the use of PAWS.

In Figure 6 and 7 the first steps for creating a weigted transition system are illustrated. After generating a matrix, the user can choose one of the available algorithms and wait until the result of the computation is displayed inside the text area (Figure 10).

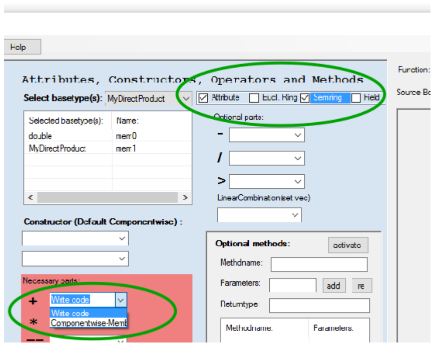

Figure 4: Top ellipse: Specify the type of the class. Bottom ellipse: Select *write code* to implement the addition (+).

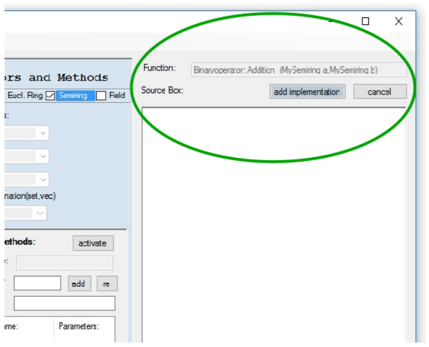

Figure 5: The text box for entering source code will be enabled after selecting *write code* as shown in Figure 4.

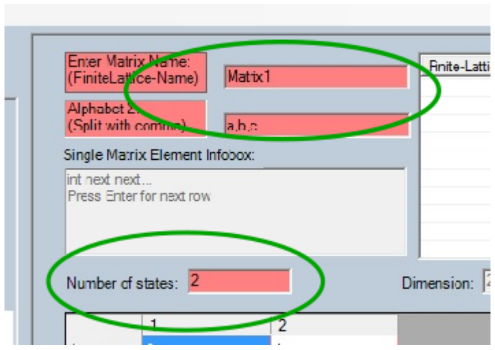

Figure 6: Top ellipse: First determine the name. Bottom ellipse: Type in the number of states.

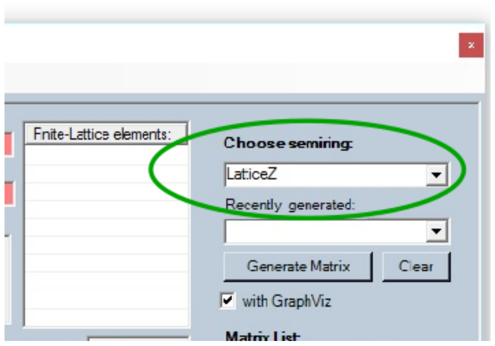

Figure 7: Choose the semiring.

With the PAWS analysis component, besides automata, also finite semirings can be generated and stored for further semiring generation as well as for the analysis.

5 Conclusion, Future Work and Related Work

We have seen that PAWS is a flexible tool to analyse the behaviour of weighted automata and conditional transition systems. The generic approach allows for adding new semirings with a varying degree of support by the tool itself.

Concerning related approaches, we are not aware of analysis tools for language equivalence and the threshold problem for weighted automata.

For the problem of generating semirings dynamically, there exists previous work for solving fixpoint equations over semirings by Esparza, Luttenberger and Schlund [13]. In [13] FPSOLVE is described, a C++ template based tool for solving fixpoint equations over semirings. That is, the tool has a different application scenario. However, the tools share similarities since in FPSOLVE the user also has the possibility to generate new semirings. For this, only the addition, multiplication and Kleene star must be implemented. However, a string constructor must also be specified without automatic support and the main method must be adjusted with the corresponding command-line. PAWS is designed to enable the

generation of new semirings for solving linear equations using a graphical user interface and does not change already existing code, which is not part of a semiring class.

In contrast to this, work has already been done on an analysis tool for featured transition systems – which are basically CTS without a notion of upgrades – to analyse software product lines wrt. simulation. In their work [8], Cordy et al. have implemented their model using BDDs as well, yielding a similar speed up as our own approach. The significant differences here lie in the notion of behaviour, since Cordy et al. have focused on simulation relations, whereas we are concerned with bisimulations. Furthermore we capture a notion of upgrade and thus support partial orders of products instead of just abritrary sets of products.

We intend to develop PAWS further in several ways. We are looking for new classes of semirings where solutions of linear equations can be effectively computed, in order to equip those semirings with an improved support from PAWS. Furthermore, we are interested in analysing more extensive case studies, where we will use PAWS to conduct all required analyses.
